Modelling of Cognitive Processes

Test 2, December 2019

**You have 1 hour** for this test. You can look up info online during the test. You are also allowed to use code from the practical sessions, or code you wrote earlier.

Comment your code, and make sure it runs. A code that does some of the parts of the test but runs, is better than a code that "can potentially" do everything but does not run. Also, even if does not run properly, send us the last version of your script with comments so we can evaluate what you were trying to do.

Note that the problem statement consists of 2 pages.

## Problem statement

Human children learn throughout their childhood what makes a sentence grammatical. This process is quite interesting, but we are not quite sure whether learning grammar is a linearly separable problem or not. Therefore, we ask you to help us out.

In the world this test was made in, a sentence is considered grammatical when the first and the last word are the same. For simplicity, we will assume that we only have 3 words: A, B, and C. Further, sentences are always composed of three words. So, grammatical sentences are ABA or CAC (for example); ungrammatical ones would be ABC or BAC.

## The steps you should take:

- Find a way to generate all possible sentences that can be formed. You should have 3<sup>3</sup>
  (27) different sentences. Higher scores are awarded if your code is easy to generalize to different numbers of words or words per sentence.
- 2. Make sure that your sentences are translated into appropriate patterns that can be presented to your model. Do *not* code your sentences as strings (['A', 'B', 'A'] to represent the sentence 'ABA' will not work), or integers ([1,2,1] to represent the sentence 'ABA' will not work). Try to work with arrays of 0's and 1's to represent words, and their position in the sentence.
- 3. Make an input array by repeating each possible input 50 times. So, your final input array should have a shape[0] of 1350 (50 x 27). Make an associated output array (1 if the sentence is considered grammatical, 0 if otherwise).
- 4. Train a two-layered Perceptron 50 times on the data. For each model fit use a different training- and test set. Training set size should be 60% of the total data set each time. Print the average accuracy for your Perceptron (across the 50 data sets). At the top of your script (i.e., before any actual code!), write down what you conclude from your output, and why you find this logical (or not). Also check with your code if it makes a difference whether your Perceptron has a bias unit or not; also explain at the top of the code, why this is so. (Clearly write "Q4: Response" at the top of your code.)
- 5. Fit a three-layered model using a module we used in class. Find the minimal model: the model with the lowest number of hidden units that is able to achieve at least % accuracy across the 50 data sets. Note again that the training- and testing set should be different for the 50 runs.
- 6. Based on your results from step 5, describe why the three-layered model has a worse / equal / better performance than the two-layered one. (Clearly write "Q6: Response" in your code).
